Abstract

The Stowage Stack Minimization Problem (SSMP) investigates a stowage planning problem when carriers have the obligation to ship all the given containers in different ports, with the objective to use the fewest number of stacks on the ship. This problem is important since it helps shipping forwarders estimate the shipping space of each shipper. To the best of our knowledge, we are the first that propose SSMP in the academic community.

In this paper, we talk about SSMP with a K -rehandle constraint. A heuristic algorithm is put forward to construct solutions. We discuss the theoretical performance guarantee of the algorithm using mathematical inequations and induction. To evaluate the actual performance of our algorithm, we conduct experiments on a set of instances with practical sizes and compare the results when different values of K are selected. What is more, instances with different numbers of ports, containers and limit heights are tested to ensure the universality of our algorithm.

Key words: Containership stowage planning, stack minimization, K-rehandle, constructive heuristic

1. Introduction

International trade plays an important role in the development of world economy. Maritime transport is the backbone of globalization and lies at the heart of cross-border transport networks that support supply chains and enable international trade. Nowadays, over 80% of world trade is carried by the maritime freight industry (Zhang & Lee, 2016). World seaborne trade volumes surpassed 10 billion tons in 2015, which is shown in UNCTAD (2016).

Container shipping is a kind of modern transportation mode which has a lot of advantages in speed, security, and quality compared with the break-bulk cargo ship. Containerization has become a mainstay of worldwide trade. This mode is deeply accepted by shippers and carriers, and is becoming the main trend of

freightage in the world. It has resulted in a tremendous growth of the maritime freight industry and it shows powerful vitality and promising prospects.

Over the past decades, there has been a continuous increase in the demand for cost-efficient containerized transportation. Thus, it makes higher research demand. The container stowage plan is a pivotal link to container transportation and the objective is to draw the loading and discharging sequence of containers for containership (Zhang et al., 2008). The most frequently used addressing notation for storage locations in a container ship is the bay-row-tier system. The cargo space of a container ship is split into several 20-ft-long areas. These areas are termed as 20-ft bays. Figure 1 reproduced from Delgado et al. (2012) shows a diagram of containership.

Figure 1: The arrangement of cargo space in a container vessel.

Each bay consists of container stacks placed along the width of the ship. Stacks in a bay are indexed by a row number. The position for one 20-ft container on the ship is uniquely indexed by (bay, row, tier), called a slot. In addition, for some ships, two contiguous 20-ft bays form a 40-ft bay which can be used to accommodate a 40-ft container.

A ship usually calls a sequence of ports and containers are loaded and unloaded at each port by cranes in a last-in-first-out (LIFO) manner. Rehandles arise either when we want to unload containers destined for the current port which however are beneath those destined for subsequent ports, or when we want to reorder the sequence of containers to prevent more rehandles in the future. Rehandles are expensive, since on one hand terminals directly charge the carriers for such operations, on the other hand, rehandles make ships dwell at terminals longer, inducing more berthing cost.

Containership stowage plans determine the number of rehandles. How to minimize the number of rehandles has troubled and aroused the interests of both scholars and commercial shipping organization in many countries (Ding & Chou, 2015; Zhang & Lee, 2016; Zehendner et al., 2017). However, previous research do not consider saving stacks, i.e., stacks on a ship can be used arbitrarily.

In this paper, we investigate the problem from a new perspective. We deal with Stowage Stack Minimization Problem (SSMP) which minimizes the number of used stacks while regarding the number of rehandles as a constraint. The problem is of practical significance. In the real world, a carrier/forwarder may evaluate needed space (stacks) for the by-far collected containers, in order to estimate how many containers can be

collected in the future; or on the contrary, a carrier/forwarder would like to receive provisional shipment orders as many as possible while reserving enough space for regular shipment orders. Our algorithm provides them an indicator to achieve such goals.

The contribution of our paper lies in three aspects. First, to the best of our knowledge, our paper considers the number of stacks used for the first time, and this is a very practical consideration. As is shown above, previous research usually focuses on how to reduce the rehandles or shifts. Second, we analyze SSMP and give upper and lower bounds of SSMP. The bounds pave a way for future study. Third, we propose a heuristic algorithm to solve SSMP and we prove that the algorithm has a performance guarantee.

The remainder of this paper is organized as follows: we review related research works in Section 2. The formal definition of SSMP and its properties are provided in Section 3. In Section 4, we present our heuristic algorithm and the performance analysis. Experiments are illustrated in Section 5. Concluding remarks close the paper in Section 6.

2. Literature review

Based on the container handling locations occurred, the container handling problems can be divided into two streams; one is container management at terminals, and the other is containership stowage problems (CSP). The problem discussed in this paper belongs to the latter.

Simulation methods based on probability, expert systems, decision support systems were mainly used in the early stages of the research. Webster & Van Dyke (1970) first tried to solve the problem by using simulation methods with the help of computer. Shields (1984) introduced a computer preplanning system (CAPS) which had been used by American President Lines. The CAPS produced stowage plans by using Monte Carlo theory. Dillingham & Perakis (1986) introduced their researches on expert system of stowage based on rules. Each of the suggested container movements was displayed graphically as the decisions were made. Wilson et al. (2001) outlined a computer system that generated good sub-optimal solutions to the stowage pre-planning problem. The methodology progressively refined the arrangement of containers within the cargo-space of a container ship until each container is specifically allocated to a stowage location.

Most existing methods for the CSP are mathematical programming approaches. Botter & Brinati (1991) created a mathematical model for the stowage plan problem, which used binary decision variables to determine the containers unloading and loading sequence for each port. A 0-1 binary linear programming formulation was presented in order to minimize the number of shifts in Avriel et al. (1998) and Avriel et al. (2000). Haghani & Kaisar (2001) proposed a MIP model for developing loading plans in order to minimize the time that a vessel spent at each port and the container handling cost. The cost was highly influenced by the number of unproductive but necessary arrangement of containers. In Ambrosino et al. (2004), the problem

of stowing containers into a container ship had been faced by evaluating an exact 0-1 Linear Programming model, which was not practically useful for large cases. Ambrosino et al. (2015) proposed a Mixed Integer Programming (MIP) heuristic aimed at determining stowage plans in circular routes for container ships so as to give support for the ship coordinator and the terminal planner. In Parreno et al. (2016), they focused on the slot planning phase and presented a Constraint Programming and Integer Programming model for stowing a set of containers in a single bay section.

Apart from mathematical programming approaches, heuristic algorithms are also widely used in the research of CSP. Three heuristic rules were used to assign gradually each type of containers to slots of the ship by four steps in Scott & Chen (1978), while the shifting problem had not been considered in their model. Tabu search was employed to obtain an optimal solution in Wilson et al. (2001), Bortfeldt et al. (2003) and Monaco et al. (2014). Ding & Chou (2015) developed a heuristic algorithm which can generate stowage plans with a reasonable number of shifts for such problems. The algorithm, verified by extensive computational experimentations, performed better than the Suspensory Heuristic Procedure (SH algorithm) in Avriel et al. (1998), which was a dynamic slot-assignment scheme. The presented hybrid GA for loading a single container in Bortfeldt & Gehring (2001) was particularly suitable for strongly heterogeneous containers stowage problems. Dubrovsky et al. (2002) used a GA for solving the stowage planning problem of minimizing the number of container movements. Search space was significantly reduced by a compact and efficient encoding scheme. The variant tackled in Cohen et al. (2017) involved several constraints, inspired by real-life problems and application found in the literature.

Other literatures about containership stowage problems considering the number of rehandles are listed as follows. Malucelli et al. (2008) investigated stack reordering strategies aiming at minimizing the number of loading and unloading operations. The complexity of stowage planning problem is investigated in Tierney et al. (2014) and it showed that the capacitated k-shift problem is solvable in polynomial time for any choice of stacks and stacks capacities. A multi-objective ship stowage planning problem was researched by Zhang & Lee (2016) and it aimed to optimize the ship stability and the number of rehandles simultaneously.

To the best of our knowledge, only Avriel et al. (2000) and Jensen (2010) discussed the stowage stack minimization and its connection with the chromatic number of circle graphs when the stack height is unlimited apart from the SSMP-ZR researched by Wang et al. (2014).

3. Problem description and properties

3.1. Problem description and notation

We put forward a detail description of SSMP in this subsection. Literally speaking, SSMP is a variant of CSP. A ship starts its journey at port 1 and sequentially visits port 2, 3, ..., P . We assume the ship stops

at port P . N containers in total are shipped along the journey. At each port, the containers destined to the current port are discharged, and the containers await on yard are loaded to the ship. We use $O(c)$ and $D(c)$ to denote the original and destination ports of container c , respectively. Accordingly, the itinerary of a container is represented by a tuple $\{O(c), D(c)\}$. Given N containers to be shipped, the objective of SSMP is to figure out a stowage planning so as to minimize needed stacks.

If two containers $c1$ and $c2$ satisfy $O(c1) < O(c2) < D(c1) < D(c2)$, and $c2$ is placed above $c1$, then one *rehandle* occurs, as we have to move $c2$ to the yard temporally for retrieving $c1$. Besides, containers above $c2$ also have to be moved, and therefore also extra rehandles occur. In this paper, we extend SSMP with zero rehandles constraint in Wang et al. (2014), assuming that K rehandles are allowed.

Other assumptions are given in this paper:

- All containers are uniform standard 20-ft containers;
- The information of containers at all ports are known in advance;
- The containership is large enough to accommodate all the given containers;
- Each stack can hold at most H vertically piled containers, i.e., the limit height of each stack is H ;
- The balance of the containership can be resolved by assigning container stacks and water-ballast; hence, the balance is not considered when minimizing container stacks.

If the number of containers in a non-empty stack is less than H , the stack is termed as a *partial* stack; otherwise it is a *full* stack. If a rehandle occurs, containers above are called *blocking containers* and the to-be-retrieved container is called a *target container*. When moving blocking containers back to the ship, there is no guarantee that they will be returned to their original slots.

A feasible solution to the SSMP is represented by a sequence of operations. The serial numbers of containers and their slots change are recorded in the operations. Especially, the yard is termed as stack 0. Moving a container c to stack 0 means that c is a blocking container and moved temporally on the yard.

3.2. Integer model

For the special case with zero rehandles, we only need to consider the loading process. For the unloading process, containers can be discharged in order without any problem. The following IP model decides the accommodating stack of each container.

In the following model, M is a sufficiently large number and S is the number of stacks on the ship. x_{is} is a binary decision variable which is equal to 1 if container i is loaded to stack s , and 0 otherwise. y_s is a binary decision variable that is equal to 1 if stack s is used for stowage, and 0 otherwise. $O(i)$ and $D(i)$ indicate the

shipping leg of container i . The objective minimizes the number of stacks used. Constraints (1) ensure that each container i is loaded to only one stack. Constraints (2) guarantee that containers can only be loaded to used stacks. Constraints (3) assure that at each port p , the number of containers in stack s does not exceed H . Constraints (4) avoid rehandle requiring that container i is prohibited to block container j in the same stack when $O(j) < O(i) < D(j) < D(i)$.

$$(IP) \quad \min \quad \sum_{s=1}^S y_s$$

$$\text{s.t.} \quad \sum_{s=1}^S x_{is} = 1, \quad \forall 1 \leq i \leq N \quad (1)$$

$$\sum_{i=1}^N x_{is} \leq M y_s, \quad \forall 1 \leq s \leq S \quad (2)$$

$$\sum_{i: O(i) \leq p \leq D(i)-1} x_{is} \leq H, \quad \forall 1 \leq s \leq S, 1 \leq p \leq P \quad (3)$$

$$x_{is} + x_{js} \leq 1, \quad \forall 1 \leq s \leq S, 1 \leq i, j \leq N, O(j) < O(i) < D(j) < D(i) \quad (4)$$

$$x_{is}, y_s \in \{0, 1\}, \quad \forall 1 \leq s \leq S, 1 \leq i, j \leq N \quad (5)$$

The IP solution can be converted into a complete loading planning from port $p = 1$ to port $p = P$. At an arbitrary port p , containers are sorted in a descending order of destination ports. Each container i is loaded to the top of its corresponding stack s^* which satisfies $x_{is^*} = 1$.

For the IP model of general SSMP, it is hard to build a model. Since there are rehandles, we have to move blocking containers in the yard and back to the ship. The stacks of blocking containers are not necessarily the original slots. If we want to model the slots of blocking containers, we have to set the variable x_{ctl} that indicates the slot t of a container c at a layout l . We do not know which containers are blocking containers in advance, therefore the domain of c is the whole set of N containers. Especially, whenever we load or discharge a container, it forms a layout. In addition, we do not know the number of layouts in advance. All in all, the number of slots, containers, and layouts are numerous. Apart from other variables and constraints, the number of variable x_{ctl} alone is too large to make the model meaningful and solvable.

4. Methodology

In this section, we will talk about the heuristic algorithm to solve the SSMP as well as the performance guarantee of the algorithm.

4.1. Heuristic algorithm for the SSMP

We first give some related notations for ease of exposition.

- K represents the number of allowed rehandles given in our problem.
- k represents the number of real rehandles and it ranges from zero to K .
- $nearport_s$ represents the value of the nearest port of stack s .
- $NumofStack_p$ is referred as the largest number of used stacks after the ship's departure from port p .
- $loading_equalK(c)$ is adapted to choose a stack for the loading container when the number of rehandles equals to K .
- $loading_lessK(c)$ is adapted choose a stack for the loading container when the number of rehandles is smaller than K .

Here is a simple example to illustrate $nearport_s$. Three containers are stored in stack s , and their destination ports are 4, 5, 6, respectively, then the value of $nearport_s$ is 4. In particular, the value of $nearport_s$ of an empty stack s is set as $P + 1$.

Algorithm 1 solves instances of SSMP and its steps are described as following.

Algorithm 1 A heuristic procedure for the SSMP

HEURISTIC(I)

- 1 **for** each port $p = 1, 2, \dots, P$
 - 2 Unload containers with $D(c) == p$.
 - 3 Sort containers with $O(c) == p$ by the decreasing order of their destinations.
 - 4 **for** each container c with $O(c) == p$
 - 5 **if** $k == K$
 - 6 execute method $loading_equalK(c)$.
 - 7 **else** If $k < K$
 - 8 execute method $loading_lessK(c)$.
 - 9 figure out the value of $NumofStack_p$.
 - 10 Output the value of $NumofStack_p$ in instance I.
-

The main two stages in our heuristic algorithm are unloading and loading procedures. Given an instance I, for each port p along the voyage, containers with $D(c) == p$ are discharged one by one firstly. Especially, if there exist blocking containers, they are moved on the yard temporally and regarded as containers to be loaded at the current port. After containers with $D(c) == p$ are discharged, containers in the yard (including containers with $O(c) == p$ and blocking containers) are sorted in order and loaded.

At the end of our algorithm, the value of $NumofStack_P$ is given as an output after all the containers are processed at the last port P .

Apart from the heuristic algorithm, we also design a random algorithm to enrich our research and it can be a reference when we conduct our experiments.

4.2. Detail description of loading procedure

Two different methods based on our greedy rules are adopted to choose a stack for each loading container according to the relationship between k and K when loading containers at each port. They are referred to as *loading_lessK(c)* and *loading_equalK(c)*, respectively. The detail description of the two loading methods will be introduced in this section.

We firstly talk about the simple condition that the allowed rehandles run out, i.e. $k = K$. In the *loading_equalK(c)* method, we first consider choosing a stack from partial stacks with $nearport_s \geq D(c)$ for the loading container c . If there are no such partial stacks, then one empty stack is necessary. Therefore, the stack selection priority for container c under this condition is:

1. the set of partial stacks, each stack s in which satisfies the constraint that $nearport_s \geq D(c)$.
2. the set of empty stacks.

Afterwards, we talk about the complex condition when $k < K$. In the *loading_lessK(c)* method, the types of feasible stacks increase as a result of the existence of rehandles. Under this condition, the stack selection priority for container c becomes:

1. the set of partial stacks, which is indexed as S_1 , each stack s in S_1 meets the constraint that $nearport_s \geq D(c)$.
2. the set of partial stacks, which is indexed as S_2 , each stack s in S_2 meets the constraint that $nearport_s < D(c)$.
3. the set of empty stacks, which is indexed as S_3 .

We need to clear all sets of stacks once we have chosen a stack for each loading container at every port for both method *loading_equalK(c)* and *loading_lessK(c)*. Of course, we will update the value of k if there is a rehandle when loading containers. After loading the current container into the chosen stack s^* , the height of s^* and $nearport_{s^*}$ should both be updated.

It's worth mentioning that our algorithm can figure out the detailed location changes of each container and output the layout status in the containership at an arbitrary time. In other words, we can predict the real-time container stowage process before the voyage as long as we know some information in advance. Therefore, our research is useful in the real application.

4.3. Performance Guarantee of the Algorithms

In order to show that our heuristic algorithm has a performance guarantee, we prove the bounds of feasible solutions to the problem. For ease of exposition, we first give some related notations.

- C^* : the optimal solution to the SSMP instances.
- C : the solution to the SSMP instances by the algorithm.
- N_p : the number of containers on the ship before its departure from port p .
- V_p : the number of loading ports that the ship has visited before it departs from port p .

It should be noted that a port is called a loading port if there exists at least one container to be loaded. Clearly, $V_p \leq p, \forall p = 1, \dots, P$.

Proposition 1. *The SSMP instance has a lower bound:*

$$\max_{p=1, \dots, P} (\lceil \frac{N_p}{H} \rceil) \leq C^*$$

Proof. $\lceil \frac{N_p}{H} \rceil$ is the least number of stacks to accommodate all the containers at port p , and thus, $\max_p (\lceil \frac{N_p}{H} \rceil)$ is the least number of stacks needed throughout the journey. \square

The lower bound can be a reference to check the optimality of solutions obtained by our heuristic. We can conclude that the solution is close to optimal if the solution is close to the lower bound.

In order to facilitate the solution, we divide the stack used in the port into two parts: full stacks and partial stacks. For the full stacks, the number of full stacks in port p is no greater than $\lfloor \frac{N_p}{H} \rfloor$, which is easy to be proven. For the partial stacks, we define the number of partial stacks in port p as $P(p)$, and we have Proposition 2 for $P(p)$.

Proposition 2. *The number of partial stacks in port p is no greater than V_p :*

$$P(p) \leq V_p$$

Proof. We divide the stacks into different partitions to store containers according to V_p (the number of loading ports) to get this proposition proven. Actually, the number of partitions is equal to V_p (the number of loading ports).

A new partition will be assigned when the ship arrives at a loading port. In every partition, there will be no rehandles since all containers at each port is sorted in order before being loaded. If it is not a loading port, there is no need to divide a new partition and the number of partial stacks will not change. If it is a loading port and the number of containers to be loaded happens to be an integer multiple of limited height H , then the number of partial stacks in the new partition is zero. Otherwise, a new partial stack will be produced in the new partition. Therefore, the number of partial stacks in a new partition during the loading process is no greater than one at every port.

Similarly, the number of partial stacks in each partition is still no greater than one after discharging containers. If there are no containers to be discharged at the current port, the number of partial stacks in each partition is the same as the former port. Otherwise, the number of partial stacks in each partition will convert between zero and one or stay unchanged. In a word, the number of partial stacks in each partition is one at most and thus the total number of partial stacks after the unloading process is no greater than the number of partitions, i.e. the number of loading ports.

We use an inductive proof.

Basis: For $p = 1$, without loss of generality, we assume that port 1 is a loading port, and therefore $V_1 = 1$. In addition, $P(1) = 0$ or 1 , i.e. $P(1) \leq 1$. Hence, $P(p) \leq V_p$ holds.

Inductive step: Suppose that the partial stacks in port i is no greater than V_i , i.e. $P(i) \leq V_i$. Upon the ship arrives at port $i + 1$, it first unloads containers with $D(c) = i + 1$ at each partition. After unloading containers with $D(c) = i + 1$, the number of partial stacks at all the partitions is still at most V_i , the number of loading ports.

(1) If there are containers to be loaded at port $i + 1$, they will be loaded into the new partition for $p = i + 1$ and there will be at most one more partial stacks to be produced, then $V_{i+1} = V_i + 1$, $P(i+1) \leq P(i) + 1$. Hence, $P(i+1) \leq P(i) + 1 \leq V_i + 1 = V_{i+1}$

(2) If there is no containers to be loaded at port $i + 1$, $V_{i+1} = V_i$, $P(i+1) \leq V_i$. Hence, $P(i+1) \leq V_i = V_{i+1}$.

Based on the above two steps, we have $P(p) \leq V_p, \forall p = 1, \dots, P$. □

Proposition 3. *For the heuristic solution to the SSMP instance, it holds*

$$C^* \leq C \leq \max_{p=1, \dots, P} (\lfloor \frac{N_p}{H} \rfloor + V_p) \leq C^* + V_P$$

Proof. The first inequality obviously holds.

For the second inequality, $C = \max_p C_p$. Noted that C_p is the number of used stacks in port p obtained from our algorithm and it includes the number of full stacks and the number of partial stacks. As the number of full stacks in port p is no greater than $\lfloor \frac{N_p}{H} \rfloor$ and the number of partial stacks in port p is no greater than

V_p . Therefore, the second inequality holds. For the third inequality, $\lfloor \frac{N_p}{H} \rfloor \leq \lceil \frac{N_p}{H} \rceil$, and $\lceil \frac{N_p}{H} \rceil$ is the lower bound of the number of stacks used at port p by Proposition 1. Thus, $\lfloor \frac{N_p}{H} \rfloor \leq C_p^*$. It then holds $\max_p (\lfloor \frac{N_p}{H} \rfloor + V_p) \leq \max_p (C_p^* + V_p) = C^* + V_P$. \square

The above propositions show that our heuristic algorithm has a constant performance guarantee. In the real shipping transportation, the number of ports is generally much smaller than the number of used stacks. Therefore, the difference between the optimal solution and our heuristic solution is relatively small, which indicates that our heuristic algorithms can generate promising solutions.

5. Experiments and Analysis

This paper uses the test data from Wang et al. (2014) and we add an important variable K into the previous instances in order to meet the demands of research. K means the number of allowed rehandles in our paper and it has a significant influence on our research. Particularly, we regard instances with $K = 0$ as the benchmark instances comparing with the same instances with different values of K . In fact, the problem becomes SSMP-ZR when $K = 0$. There are 360 sets of instances, or 1800 instances in total, which are categorized by four parameters: the number of allowed rehandles, which is selected from $\{0, 10, 20, 50, 100\}$; the number of ports P , which is selected from $\{5, 10, 20, 30\}$; the number of containers N , which is selected from $\{50, 100, 200, 500, 1000, 5000\}$; and the limit height H , selected from $\{4, 8, 12\}$. Each set consists of 5 instances generated by different random seeds. In each instance, the origin $O(i)$ and the destination $D(i)$ of a container i are generated from a uniform distribution on the integers $1, 2, \dots, P$ satisfying that $O(i) < D(i)$.

In this section, we will showcase the performance of our heuristic algorithms and random algorithm on a number of test instances. The heuristic and random algorithms were implemented in Java and the experiments were conducted on a computer with Intel Core processor clocked at 2.30 GHz and 8 GB RAM. The operating system of the computer is Windows 10. For better description of our experimental result, we only show the average value of $Numofstack_P$ when $K = 0, K = 10, K = 20, K = 50, K = 100$, respectively.

The experimental results are shown in Table 1 and Table 2. Considering the size of the table, the results of instances with $N = 5000$ are not listed.

Table 1 summarizes the results of those easy instances with smaller number of ports, i.e. $P \in \{5, 10\}$. For each given P, N and H , we work out the values of LB, UB of our heuristic algorithm. For both our heuristic algorithm and random algorithm, we work out the average numbers of $Numofstack_P$ in different instances when K is set to different values. The LB and UB are used to test the rationality of heuristic algorithm and the average $Numofstack_P$ of instances with different values of K by using heuristic and random algorithms are used to compare with each other.

Table 1: Results of the instances with $P \in \{5, 10\}$

Table 2 summarizes that the results of those difficult instances with larger number of ports, i.e. $P \in \{20, 30\}$. The columns in Table 2 are similarly defined as those of Table 1 and so is the conclusion we can get from Table 1.

Most of the instances provide the evidence that it works better when K is not equal to zero comparing the condition where K is equal to zero. However, the result of easy instances is somewhat different from the result of difficult instances. Comparing with the significant influence of different K in the difficult instances, the influence of different K in easy instances is not so obvious. The same conclusion can be drawn if we focus on every single variable or factor while keeping other variables unchanged.

After repeated experiments and process analysis, we draw the conclusion that the distribution of containers in each stack accounts for this phenomenon. In other words, the value of variables get smaller, the same kind of containers with the identical origin port and destination port have more chance to be placed in the same stack and less rehandles will arise. We call this kind of stack with high density, and high sparseness in contrast.

For each instance with the same P , N and H , we call it benchmark instance when K is equal to zero. When K is not equal to zero in an instance, we call it an exceptional instance if the number of used stacks is larger than the result of its benchmark instance. There are few exceptions when we analyze the result through a large number of experiments. Comparing the condition with zero rehandle, the number of needed stacks is even larger when the number of allowed rehandle K is not equal to zero, though the deviation is not large.

We then find out those exceptional instances and compare the stowage planning with the same instances under the zero rehandle constraint, and we find it is the distribution status of previous containers to make a difference. In fact, the allowed rehandles delay the production of new stacks but not to reduce them, that is why the problem happens. After all, it's the unloading strategy for blocking containers that causes this exceptional condition. Because we reset the origin port of blocking containers, the loading containers in current port increase and meanwhile the allowed rehandles run out. In the end, the extra and new stacks are needed under this circumstances. In order to prove it, we output the layout of the exceptional instances and the corresponding benchmark instances. By comparing the layout between exceptional instances and the corresponding benchmark instances, we get the conclusion that both the distribution of containers and the algorithm result in this kind of abnormal condition.

However, it does not mean that our algorithm is inapplicable or our algorithm does not have a universality because the probability of causing exceptional instances is very low and it hardly happens in our practical operations. Actually, our heuristics algorithm is feasible for most of the instances and has a good performance as well. The following tables and figures can be used to illustrate the good performance of our algorithm.

Table 3 and Figure 2 give the average results of heuristic and random algorithm when the number of allowed rehandle K is set to different values. It's not difficult to draw the conclusion that the number of

Table 3: average results of the instances with different K for two algorithms

K	0	10	20	50	100
<i>Numofstack</i> of Heu	99.3	99.21944	99.08333	98.73889	98.35
<i>Numofstack</i> of Ran	114.62778	114.31667	114.21448	112.86111	111.9

Figure 2: Numofstack of Heu and Ran with different K.

used stacks gets smaller as the allowed rehandle becomes larger for both heuristic algorithm and random algorithm. Another conclusion is, comparing with the random algorithm, our heuristic algorithm has a fairly good performance to work out the solution. It's noteworthy that the average results in Table 3 include the instances with $N = 5000$.

There is a simple illustration to explain why a certain number of allowed rehandles can improve the utilization of containership comparing with the condition with zero rehandle. Assuming that there are thirteen containers to be transported along the voyage with six ports. We let $C(i,j)$ denote index container whose origin port is i and destination port j . The following is the way to denote those containers: four containers are $C(1,3)$, one is $C(2,4)$, one is $C(2,6)$, four are $C(3,5)$, one is $C(4,6)$ and two are $C(5,6)$.

If they are loaded without any rehandles, the loading sequence and layout will be the following Figure 3.

Figure 3: stowage plan without rehandles.

If they are loaded with enough rehandles, the loading sequence and layout will be the following Figure 4.

Figure 4: stowage plan with rehandles.

From Figure 3 and Figure 4, we can clearly get the conclusion that allowing a certain number of rehandles will reduce the number of stacks used to store containers in a vessel compared with the condition with zero rehandle. In other words, the utilization of containership can be improved if some rehandles are allowed.

As a matter of fact, we have tried a related algorithm named $P\&H$ algorithm to get the optimal stowage planning before adopting our current heuristic algorithm. This algorithm is actually a process of parameter tuning, our original intention is attempting to find out a better solution to stow containers. Nevertheless, the result of this algorithm is not as good as the heuristic algorithm and it does not work well as we expected if the value of K is small. From another point of view, it just shows the good performance of our heuristic algorithm.

In our $P\&H$ algorithm, we give some restrictions on the height and the destination port of current loading container when choosing an optimal stack for current loading container. Both the parameters in $P\&H$ value between 0 and 1, and zero is not included. The former parameter represents the ratio of the $D(c)$ and the farthest port P , c is the sequence number of current loading container. The value of this parameter is 1 if $D(c) == P$. The latter parameter represents the ratio of feasible stack's height and the limited height H . The main idea of the $P\&H$ algorithm is to take the destination port of loading container and the limit height of stack into consideration when choosing the best stack for each loading container. The purpose of this algorithm is to load those containers with farther destination port into the bottom of the stack and the computational result is shown in Table 4.

Table 4: average results of the instances with $P\&H$ algorithm

$P\&H$	0	10	20	50	100
0.75&0.75	99.32222	99.24167	99.08056	98.725	98.29167
0.75&0.80	99.32222	99.24167	99.08056	98.725	98.29167
0.80&0.75	99.30833	99.225	99.05556	98.71111	98.31389
0.80&0.80	99.30833	99.225	99.05556	98.71111	98.31389

It's noteworthy that the average results in Table 4 include the instances with $N = 5000$ and the values of two parameters in the $P\&H$ algorithm are both selected from $\{0.75, 0.8\}$. It's clear that the result shows the allowed rehandles will decrease the number of used stacks as the above results in Table 3. What's more, we can draw a conclusion that the first parameter has a significant influence on the result while the second parameter makes no difference if we compare the result in each row.

Figure 5: comprehensive analysis.

Figure 5 is made to find the relationship between the related variables and the results obtained from our heuristic. K is selected from $\{0,100\}$, P is selected from $\{5,30\}$, N is selected from $\{50,200\}$ and H is selected

from {4,12} in Figure 5 so that we can find out the related relationships clearly.

Observing from Figure 5, we can get the following relationships. On one hand, the more ports, the more containers and the higher limited height will result in the more needed stacks whether we consider the influence of univariable or multivariable. On the other hand, the difference in the results between zero rehandles and certain allowed rehandles becomes more and more obvious as the number of ports gets larger, the limited height gets higher and the number of containers gets smaller.

In short, the good performance of our heuristic have been confirmed by all the above tables and figures.

6. Conclusion

The stowage stack minimization problem with K -rehandles constraint is aimed to find out a stowage plan that the fewest stacks are used on a containership throughout a voyage by subject to K -rehandles. Actually, the stowage stack minimization problem with zero rehandle is regarded as a particular case of SSMP when K is set to zero. The other way round, the problem proposed in this paper is a generalized and extended problem of SSMP-ZR considering the existence of K rehandles.

In this paper, we first presented the integer programming model for the SSMP-ZR in Wang et al. (2014). However, it is hard to build an IP model for the stowage stack minimization problem with K -rehandles. A heuristic approach is then proposed to construct solutions to the SSMP problem in a very short computational time. The performance guarantee of our heuristic algorithm is proven with the solution of lower and upper bounds, which pave a way for future study.

The experimental results show that our heuristic algorithm generates very promising solutions on a variety of instances. Through experimental analysis, it can be found that it is meaningful to take the number of stacks used into consideration. The results show the problem we put forward is of practical significance and it does reduce the number of stacks used and improve the utilization of containership.

The novelty and practicality show the importance of this paper and it can give a reference to future study. In the further research, more heuristic and precise algorithms will be used to find solutions to the stowage stack minimization problem. In addition, the Stowage Stack Minimization Problem in circular routes may be another interesting and meaningful research.
